Single-Chip Modem Provides Low-Cost Data Communication

A simple modem provides an inexpensive way to link your IBM PC or compatible computer with a remote system. The modem, which transmits data asynchronously at 300 baud, is easy to build and features both autodial and autoanswer.

Using a simple design, you can build an inexpensive modem for your IBM PC or compatible computer. Based on a single chip that transforms digital computer data into analog frequencies, the modem lets you transmit data asynchronously via telephone lines at 300 baud. The circuit also uses a DTMF (dual-tone multiple-frequency) tone-dialer chip, a DAA (data-access arrangement) telephone-line interface, and a UART that handles autoanswer and autodial functions. Configured to operate in your PC's I/O address space, this modem circuit uses an equality detector and a 3-to-8-line decoder to decode address lines, I/O strobes, and DMA strobes.

The modem design is based on the MM74HC942 modem chip *Figure 1* illustrates the chip's architecture. By eliminating two external op amps, an on-chip line driver and a 2-to-4-wire hybrid simplify the task of interfacing to the telephone line. The line driver drives a 600Ω line through an external 600Ω terminating resistor, thus providing a nominal impedance match between the modem and the phone line. When the programmable level-adjust resistor R_1 is connected between the TLA pin and V_{CC} , the line driver transmits at levels approaching 0 dBm.

You can access the driver externally through the DSI and EX1 pins (pins 1 and 18). The EX1 input provides a set gain

of about 2. The DSI input allows you to achieve an adjustable gain reaching 0 dBm via series resistor R_2 . The gain is approximately $20k \div R_2$.

Because the circuit communicates via 2-wire telephone lines, both incoming and outgoing signals enter the HC942. The on-chip line hybrid rejects the outgoing signal while passing the incoming signal to the demodulator. Under most phone-line conditions, the hybrid provides 10- to 20-dB transmit-carrier rejection. The receive filter of the demodulator section reduces the outgoing signal to negligible levels.

A LOOK AT THE MM74HC942 MODEM CHIP

The MM74HC942 modem IC lets you use simple support circuitry, requires relatively little circuit-board area, and consumes little power. Although the chip is functionally similar to others on the market, it includes an adjustable line driver and programmable carrier-detection circuitry, and it operates from $\pm 5V$ supplies.

The chip's analog loopback (ALB) function and power-down mode provide self-testing and power conservation. You set the ALB function by holding the ALB input high, which causes the modulator to shunt its output to the input of the demodulator, providing a simple diagnostic self-test.

The power-conservation feature makes the HC942 power down when both the ALB and SQT inputs are high. The chip typically draws less than 50 μA in the power-down mode, so, for certain applications, you might have to add a battery for backup power.

Either the ALB or the SQT input can bring the chip out of its power-down mode, so you can use the HC942 in a bus-like configuration. Because the chip's inputs and outputs offer 3-state levels, either the ALB or SQT input can serve as a chip select when one of them is low.

MODULATOR CONVERTS DATA

In the modulator section of the modem IC, the frequency synthesizer generates clock frequencies for the sine-wave synthesizer. During transmission, digital data from the CPU or UART enters the TXD input on the HC942, which converts incoming ones and zeros to mark and space frequencies, respectively. The Originate/Answer (O/A) input sets these frequencies into the upper or lower transmit bands (*Figure 2*).

FIGURE 2. The HC942 modem chip converts incoming ones and zeros to mark and space frequencies when digital data enters the chip's TXD input

FIGURE 1. The MM74HC942's 2-to-4-wire hybrid and line driver let you use simple circuitry to interface your modem to the telephone line

Printed previously by EDN

A high signal on the O/ $\bar{A}$ pin lets you originate a call. In the originate mode, the HC942 transmits in the lower band and receives in the upper band. In the answer mode, the chip transmits in the upper band and receives in the lower band. The chip's sine-wave synthesizer, which is essentially a D/A converter, decodes the output of the frequency synthesizer, producing an FSK output that's compatible with the Bell 103 standard. Table I shows the frequency assignments for both modes of operation.

Using a 9-pole switched capacitor, the demodulator passes incoming tones at the same time that it virtually eliminates locally transmitted signals. The demodulator's receive filter then transmits its output to a frequency discriminator, in which two detectors sense the mark and space frequencies, converting each frequency to a logical one or zero.

The receive filter also passes output to the carrier detector, which then compares the output of the filter with an externally adjustable voltage at the CDA pin. If you leave this pin floating or connect it to ac ground, the voltage at CDA is 1.2V. The threshold is nominally set on at -42 dBm and off at -45 dBm. When a carrier exceeds the upper threshold, the carrier detector activates the demodulator after a preset timing delay, forcing the $\overline{CD}$ output low. Timing capacitor C_6 at the CDT pin sets the carrier-detect delay. When the carrier level drops below the lower threshold point, the demodulator returns to a disabled state.

TABLE I. Bell 103 Tone Allocation

Data	Originate Mode		Answer Mode	
	Transmit	Receive	Transmit	Receive
Space	1070 Hz	2025 Hz	2025 Hz	1070 Hz
Mark	1270 Hz	2225 Hz	2225 Hz	1270 Hz

The interface hardware between the HC942 and an IBM PC or compatible computer has four major parts: the decoding logic, the communication link, the tone dialer, and the DAA (Figure 3). The decoding logic addresses the two I/O address locations on the PC that are reserved for asynchronous communications. The primary location is 3F8_{HEX}-3FF_{HEX}; the secondary location is 2F8_{HEX}-2FF_{HEX}. When the decoding logic uses these two locations, this interface design is compatible with IBM PC software. (For other address locations, consult the documentation for your computer and for any other add-in cards your computer is using.)

The interface circuit employs an HCT688 equality detector and an HCT138 3-to-8-line decoder. When you connect the IOR and IOW strobes in a NAND configuration, the circuit generates the I/O strobe while the direct-memory-access (DMA) strobe acts as the AEN output from the IBM bus. The equality detector compares its corresponding P and Q inputs and checks to see whether P equals Q. When P and Q are equal, the P=Q output selects the HCT138 decoder and the HCT245 bidirectional bus driver.

The HCT138 further decodes the address lines, selecting as many as eight devices, although it enables only two: the TP5088 tone dialer and the 8250 UART. Output Y_7 directly enables the 8250. The Y_5 output, however, indirectly enables the TP5088 via an HC123 dual one-shot. This output triggers the one-shot, which activates the TP5088 for a pre-

determined time. The lower three address lines (A_2 through A_0) access the 8250's internal registers by addressing the UART directly.

The 8250 and the HC942 provide the serial communications link between the host and remote computers. During transmission, the UART converts parallel data from the μP to serial data for the HC942. The HC942 receives this data at its TXD input and transmits an FSK output at the TXA output. During data reception, the HC942 receives incoming tones at the RXA₁ input, demodulates the tones, and sends serial data through the RXD output to the 8250.

Because the HC942 doesn't require an external line driver or a hybrid, the modem circuit requires only a few passive components. Resistor R_{12} sets the line driver's transmit level (Table II) at the same time that C_6 adjusts the carrier-detect timing circuit. This circuit waits a predetermined time (the time period is a function of the RC time constant) before responding to a carrier and sending the $\overline{CD}$ (Carrier Detected) output high. In addition, the circuit delays for a short time before dropping the $\overline{CD}$ output low again. Use the following equations to find the appropriate delay times:

$$T_{\text{OFF-TO-ON}} = 6.4 \times C$$

and

$$T_{\text{ON-TO-OFF}} = 0.54 \times C$$

where C is in μF and T is in seconds. The first equation gives the delay before transmission begins; the second gives the delay before transmission ends. Note that these times differ considerably. When the modem is preparing to transmit, it must delay long enough to ensure that the carrier is stable; carrier stability is not as critical when the modem is preparing to stop transmitting.

The HC942 uses a common 3.579-MHz crystal (without loading capacitors) to generate all the internal timing and modulated sine waves. The crystal also drives the TP5088's oscillator. It doesn't, however, drive the 8250's oscillator, because IBM PC software requires the 8250 to use a 1.8432-MHz crystal. You can adjust the carrier-detection trip points by applying an external voltage at the CDA (Carrier-Detect Adjust) pin. When you double the nominal voltage (1.2V), the trip points increase by 6 dB. Similarly, when you cut the voltage in half, the trip points decrease by 6 dB.

TABLE II. Standard Resistor Values*

*UNIVERSAL SERVICE ORDER CODE

FIGURE 3a. The interface hardware between the HC942 and the computer (an IBM PC or compatible) comprises four major parts: the decoding logic, the communication link, the tone dialer, and the data-access arrangement (DAA).

FIGURE 3b

Because the modem operates in full-duplex mode, most of the handshake signals—Data Terminal Ready (DTR), Clear To Send (CTS), etc—operate as general-purpose control signals. You need to use only the DCD (Data Carrier Detect) and RI (Ring Indication) signals. To control the modem, the UART switches the HC942 into the originate/answer mode and the squelch mode (modulator disabled) through outputs RTS and OUT1. The 8250 also closes the on/off-hook-switch relay through output DTR.

The 8250 receives status information from the carrier-detection and ring-detection circuits. When a carrier is present, the internal carrier detector of the HC942 sends a Carrier Detected signal to the DCD input port of the 8250. This signal gives the cue to begin data communication. Similarly, the ring detector in the DAA sends a signal to the RI input port during a ring signal.

The DTMF tone dialer operates by summing two tones, one from a low group and one from a high group (Table III). The tone dialer then sends the composite tone to the telephone company's central office. The TP5088, which can directly decode a 4-bit binary code, becomes active when the Tone Enable receives a low-to-high transition, and it remains active as long as the input stays high. This input is connected to the HC123 one-shot, which sets the duration of the DTMF tone. The FCC requires that tone duration have a minimum cycle time of 100 ms, a pulse duration of 50 ms, a minimum interdigit interval of 45 ms, and a maximum interdigit interval of 3 sec.

TABLE III. Functional Truth Table

Keyboard Equivalent	Data Inputs				Tone Enable	Tones Out		Mute
	D ₃	D ₂	D ₁	D ₀		f _L (Hz)	f _H (Hz)

Before coupling a tone dialer to the phone lines, you must make sure the dialer meets certain FCC guidelines. For instance, you must maintain specified dc voltages and loop currents for all loop lengths, match the impedance to the phone line, and provide tones within specified amplitude and distortion limits.

By designing the DAA correctly, you can make your tone dialer meet the first two of these guidelines. Because the 5088 generates low tone distortion, you can ignore the distortion limit. However, you must boost the 5088's output levels to the output levels shown in Figure 4. Using the inter-

nal line driver of the HC942, you can raise the 5088's minimum output level to 0 dBm. Transistor Q₄ raises the output level of the line driver to its maximum by shorting the transmit-level adjustment resistor R₁₂.

TL/F/8691-5

FIGURE 4. Although the TP5088 tone dialer allows you to ignore distortion limits, you must boost its output levels to conform with the FCC limits shown here.

DAA PERFORMS DUAL FUNCTIONS

The DAA is both a protective device and a functional modem interface. Although the DAA is simple, you should submit your final design to qualified testers to ensure that your circuit conforms to FCC rules (part 68 and part 15).

In its protective capacity, the DAA provides surge protection from natural hazards (like lightning) and from induced voltages generated by relay coils. The DAA also provides dc isolation between the phone line and the modem. Its modem-interface functions include ring detection and on- and off-hook control. The DAA's ring-detection circuit sends a signal to the CPU via the 8250 (shown in Figure 3a) when an incoming ring occurs. On- and off-hook control takes place via a relay that the 8250 controls with its DTR signal.

The DAA has three sections: the transformer, the relay, and the ring detector. The circuit's 600Ω 1:1 transformer isolates the modem from the phone lines, preventing line interference. For voice and data communication, the transformer must have a flat frequency response from 300 to 3300 Hz with little harmonic distortion. As you can see from Figure 3b, a current sink (Q₂ and Q₃) is connected in parallel with the transformer. The diode drop across R₁₈ shunts excess current.

The current flowing through telephone lines varies from 20 to 120 mA. If your design requires a transformer that can't handle at least 30 mA, you'll need to add the current sink to shunt the excess current from the phone line, preventing transformer saturation. Of course, if you were to use a transformer that could handle more than 30 mA, you wouldn't need a current sink, but the transformer would be both heavy and expensive.

A relay in the DAA provides on- and off-hook control. By closing, the relay switches the modem off-hook and connects the DAA to the telephone line. The DTR signal from the 8250 controls this relay by switching Q₄ on. This transistor allows current to flow through the relay and close its contacts. A dpdt relay completely isolates the relay-control circuit when the modem is on-hook.

The ring-detector circuit in *Figure 3b* sends a signal to the CPU via the 8250 when an incoming ring occurs. Because the incoming ring signal is nominally 90V rms, you can't couple it directly to the DAA. The ring detector includes a 27V zener diode, a capacitor (C_{10}), and an optocoupler. The zener diode prevents noise from tripping the ring detector. C_{10} creates a high dc impedance so that the ring detector won't affect other circuits in the DAA. Note that C_{10} must be able to accommodate high voltages, such as the high amplitude of the ring signals. The optocoupler provides isolation and translates the high-voltage ring signals into digital levels.

The optocoupler toggles on and off during a ring, producing a series of low-going pulses. An RC network (R_{21} and C_{11}) smoothes these pulses to a single low pulse. The 8250 receives this pulse at its $\overline{RI}$ (ring indication) input port. The μP detects the ring by polling this port or by servicing the generated interrupt.

PC EMULATES A DUMB TERMINAL

The communication program for the modem (the listing begins next page) consists of three routines (for autodial, autoanswer, and terminal emulation). The first two routines establish a connection by either dialing a number or answering a call. The main terminal routine then configures the IBM to act as a dumb terminal that transmits to the phone line all characters you enter from the keyboard and displays all incoming characters on the CRT. The program is menu driven; you select either the autodial or the autoanswer routine. At the end of these routines, control jumps either to the terminal program or to the main menu. You use the "table of equates" at the beginning of the program to set up the initialization parameters.

The communication program frequently accesses the modem registers to control outputs $\overline{DTR}$, $\overline{RTS}$, and $\overline{OUT1}$. It also polls the line status register to read status-input ports $\overline{RI}$ and $\overline{DCD}$.

When you select the autoanswer option from the menu, the routine begins by polling bit 6 of the modem's status register to detect incoming calls. When a ring occurs, this bit goes high. The modem does not immediately go off-hook, however, because the ring signal's high voltage causes arcing between the relay contacts. Instead, the program delays answering for 2.5s, lifting the modem off-hook between rings. The modem goes off-hook by setting bits 0 and 1 of

the modem's control register low. The $\overline{RTS}$ and $\overline{DTR}$ outputs, in turn, go low. These outputs then switch the HC942 into the answer mode by closing the relay to establish a connection.

After the modem answers the telephone, a 2s billing delay must occur (according to FCC regulations) before transmission can begin. During this period, the telephone company's central offices exchange the callers' billing information. A software delay keeps bit 2 of the modem's control register low, ensuring that the HC942 engages the squelch function during this period. After the billing delay, the HC942 disengages the squelch function, and the μP polls bit 7 of the modem's status register. If bit 7 is high, a carrier is present, and data communication can begin. The autoanswer routine then jumps to the main program to transmit and receive data. If the other computer fails to respond with a carrier, the autoanswer routine times out, and control returns to the main menu.

The autodial routine first asks you whether you want to make a long-distance or a local call and then enters the phone number into buffer $BUFF1$. Next, the modem dials the phone number by fetching a digit from the buffer and sending it to the TP5088. The μP then waits 200 ms. During this period, the HC123 one-shot enables the TP5088 for 80 ms and then disables it for the remaining 120 ms. Therefore, each digit comprises an 80 ms DTMF tone followed by 120 ms of silence. After the modem dials the phone number, the μP polls bit 7 in the status register to see if a carrier is present. Modem operation then takes place as in the autoanswer mode.

The main program enters either from the autodial or the autoanswer routine. It polls the line status register (LSR) and the modem's control register (MCR) to determine whether characters from the keyboard or the telephone line are present and to detect transmission errors or carrier loss. When keyboard characters are present, bit 5 of the LSR goes high; when line characters are present, bit 0 goes high. The μP then reads the characters from the UART. Bits 1, 2, and 3 of the LSR indicate transmission errors; when such errors occur, the CRT displays a question mark. Bit 7 of the MCR indicates carrier loss. If the main program detects carrier loss during transmission, it disconnects the modem and returns to the main menu.

LIFE SUPPORT POLICY

NATIONAL'S PRODUCTS ARE NOT AUTHORIZED FOR USE AS CRITICAL COMPONENTS IN LIFE SUPPORT DEVICES OR SYSTEMS WITHOUT THE EXPRESS WRITTEN APPROVAL OF THE PRESIDENT OF NATIONAL SEMICONDUCTOR CORPORATION. As used herein:

1. Life support devices or systems are devices or systems which, (a) are intended for surgical implant into the body, or (b) support or sustain life, and whose failure to perform, when properly used in accordance with instructions for use provided in the labeling, can be reasonably expected to result in a significant injury to the user.
2. A critical component is any component of a life support device or system whose failure to perform can be reasonably expected to cause the failure of the life support device or system, or to affect its safety or effectiveness.
